Abstract The future trajectory of forest ecosystems under climate change is heavily debated. Previous studies on the impacts of climate change on forest ecosystems have focused mainly on direct effects of altered climatic conditions, whereas interactions with disturbance events have been largely neglected. The aim of this study is to explore interactions of drought with fire disturbance and to assess their effects on tree species shifts in the European Central Alps. Tree recruitment after a stand replacing wildfire in the Rhone valley, Switzerland, was measured along an altitudinal temperature moisture gradient. Recruitment was more successful in pioneer species (*Betula pendula*, *Populus tremula* and *Salix appendiculata*) than in pre-fire stand forming (PFSF) species (*Larix decidua*, *Picea abies* and *Pinus sylvestris*). Seedling and sapling density was not related to fire intensity, but it correlated with the distance to the forest edge in PFSF species. The window of opportunity for seedling establishment was short (1–2 years), and moisture deficit was the main limiting factor for tree recruitment at lower altitudes. We suggest that prolonged drought periods, as projected under continued global warming, will further aggravate tree recruitment success after fire disturbance at low altitudes of the Central Alps and may eventually lead to a shift from PFSF species to either more drought-tolerant species or to forest-free vegetation.

Keywords Central Europe · Disturbance · Drought · Pine forest · Post-fire regeneration · Tree recruitment

Introduction

As a consequence of the projected long-term changes in temperature and precipitation fluctuations in Central Europe (Schär et al. 2004), climate envelope models predict major shifts of tree species' ranges both in latitude (Sykes et al. 1996; Thuiller 2003; Thuiller et al. 2006) and altitude (Brzeziecki et al. 1995; Sykes and Prentice 1996). Current evidence for future tree species' shifts is most often based on observed changes in growth rates (e.g. Jump et al. 2006), forest species composition (see review by Walther 2003), forest phenology (Badeck et al. 2004; Linderholm 2006) or tree-line movements (Kullman 2002; Payette et al. 1989), whereas reports on changes in tree recruitment are still sparse (Peñuelas et al. 2007). In practice, shifts of tree species in undisturbed forests are difficult to detect, and the speed and the magnitude of climate-induced range shifts or changes in forest species assemblages are heavily debated. Several authors suggest that increased temperatures alone will not fundamentally alter forest ecosystems, while interactions of climate change with disturbance events, by contrast, may trigger abrupt and irreversible changes in forest species composition (Chapin et al. 2004; Dale et al. 2001). The modelling study by Schumacher & Bugmann (2006) predicts that increasing temperatures in combination with fire disturbance may become a major factor shaping Alpine forest ecosystems in the future. Similarly, Overpeck et al. (1990) suggest that increased disturbance frequencies accelerate forest vegetation responses to climate change in North America. Interactions of climate change with disturbance have been largely neglected in the

prediction of the future trajectory of forest ecosystems, although some authors discussed the impact of shorter fire intervals on forest composition (Dale et al. 2001; Johnstone and Chapin 2006). However, fire may affect tree species composition much more directly and on a shorter time scale than through changes in fire frequency, e.g. by destroying the existing canopy and opening a window for the establishment of new species that are better adapted to modified climatic conditions (Overpeck et al. 1990; Tercero-Bucardo et al. 2007). Since fire frequency is currently low in Central European forests (Tinner et al. 2005), it has not been considered as important for shaping coniferous forest ecosystems as e.g. in North America (Attiwill 1994). Thus, forest gap initiation in combination with altered climatic conditions may be the main factor triggering tree species shifts in the European Alps in the short term.

Tree recruitment after fire disturbance depends on a variety of factors such as propagule availability, germination success and seedling survival and establishment (Rodríguez-Pérez and Traveset 2007). In coniferous species, propagule availability after a disturbance is primarily determined by the seed rain from live trees and the dispersal capacity of the seeds, whereas asexual reproduction and persistent seed banks are less common (Greene et al. 2005; Krüssmann 1983; Zasada et al. 1992), although aerial seed banks are known in some species (e.g. *Picea mariana* (Mill.) Britton et al. *Pinus banksiana* Lamb.; Greene and Johnson 2000). Depending on fire severity, a seedling and sapling bank may survive. In European conifers, seed germination and seedling survival after disturbance are generally thought to be favoured by a thin organic layer, exposed mineral soil and sufficient moisture (Brang 1998; Greene et al. 2005; Valkonen and Maguire 2005; Vanha-Majamaa et al. 1996), whereas the effect of mosses is not consistent (Hanssen 2003; Valkonen and Maguire 2005; Wohlgemuth et al. 2002). Studies at the southern distribution limit of Scots pine *Pinus sylvestris* L. suggest that long drought periods during the growing season, which are predicted to increase in Central Europe as a consequence of climate change (Schär et al. 2004; Schmidli and Frei 2005), may become a major threat to the establishment of conifer seedlings in Central Europe in the future (Castro et al. 2004; Castro et al. 2005).

The aim of this study is to assess whether interactions of fire disturbance with temperature and precipitation may accelerate climate-induced tree species shifts in forests of the dry valleys of the European Central Alps. We assessed recruitment success of different tree species after a stand replacing wildfire in the Valais, Switzerland, one of the driest regions in the Alps. Tree recruitment, air temperature and precipitation were quantified along an altitudinal gradient of 1,200 m (900–2,100 m a.s.l.), which corresponds to a temperature moisture gradient. We tested: (1) whether the

recruitment success of pre-fire stand forming (PFSF) tree species increases with altitude, i.e. with increasing precipitation, (2) whether tree species other than PFSF species (e.g. pioneer species) successfully establish at low altitudes, i.e. under high temperatures and low precipitation and (3) whether seedbed conditions in terms of availability of exposed mineral soil and moss cover, distance to the live forest edge or fire severity are more important for tree regeneration after fire disturbance than temperature and precipitation.

Materials and methods

Study site

The study site is located near Leuk in the Central Alpine Rhone valley in the Valais, Switzerland (46°20'N, 7°39'E; Fig. 1a). A wildfire started by arson in 2003 burnt 310 ha of forest along an altitudinal gradient of 1,200 m ranging from 900 m a.s.l. to the tree line at 2,100 m a.s.l (Fig. 1c). The pre-fire forest communities consisted of Scots pine *Pinus sylvestris* L. in the lower montane zone (900–1,300 m a.s.l.), Norway spruce *Picea abies* (L.) H. Karst. in the upper montane zone (1,300–1,700 m a.s.l.) and mixed spruce and larch *Larix decidua* Mill. forest in the subalpine zone between 1,700 m a.s.l. and the tree line (Ott et al. 1997). The pre-fire vegetation also included a small proportion of downy oak *Quercus pubescens* Willd. in the lowest parts of the study site, but the main distribution of this species is below 900 m a.s.l. Apart from the area immediately adjacent to the burn edge and a small area (ca. 1 ha) of Norway spruce and larch that survived the fire at 1,750 m a.s.l., the understory vegetation as well as the foliage and fine twigs of all standing trees was completely consumed. The fire further destroyed 80% of the soil organic layer (Wohlgemuth et al. 2005).

The upper Rhone valley has a continental climate similar to that of the Briançonnais in France and the Val d'Aoste and Vinschgau in Italy (Zumbrunnen et al. 2009), which is characterised by low precipitation levels, especially during the summer months (average annual precipitation 637 mm at 539 m a.s.l.; meteorological station Sierre, MeteoSwiss). In comparison with southern European regions (e.g. the Mediterranean basin), the fire activity in the Rhone valley is currently rather low. Between 1904 and 2006, 129 fires/100 km² of forest occurred below 1,400 m a.s.l., but only 40 fires/100 km² of forest were observed at higher altitudes (Zumbrunnen et al. 2009).

Tree recruitment survey

In 2004, 125 permanent sampling plots of 50 m² were established on a systematic grid of 125 m × 125 m within

Fig. 1 **a** Location of the study site in the inner-alpine valley of the Valais, Switzerland. **b** Locations of the 310 ha burn near Leuk and the MeteoSwiss stations in Sierre (539 m a.s.l.) and Montana (1,508 m

a.s.l.). **c** Locations of the 125 sampling plots (*small dots*) and the 13 meteorological stations (*large dots*) measuring temperature (T) and precipitation (P) within the burn

the burnt area (Fig. 1c). Distances of the sampling plots to the nearest forest edge and/or the 1 ha within-burn zone where living trees remained vary between 3 and 463 m. From 2004 to 2007, the number of seedlings (0–10 cm height) and saplings (11–500 cm height) was recorded annually for each tree species during summer season (June–August). Seedling mortality was calculated from differences between years, taking into account seedlings grown into the sapling stage. The cover of mosses, herbaceous species and exposed mineral soil (with or without ash) were estimated using the decimal scale of Londo (1976). The thickness of the ash layer in 2004 (median of nine measurements/plot) was used as an index of fire intensity (Henig-Sever et al. 2001). Because the fire was severe throughout the entire burnt area and the crowns of all standing trees were completely scorched, we could not rely on crown scorch height or similar, more commonly used measurements of fire intensity. Annual records of cone production made by A. Burkart, Versuchsgarten WSL, in Graechen and Gampel Steg, two sites in the Rhone valley near Leuk, were used to estimate seed rain of Scots pine, Norway spruce and larch in the years following the fire (2004–2006).

Climate data

The climate along the altitudinal gradient was quantified using different data sources: (1) short-term monthly average temperatures and monthly average precipitation (2005–2007) measured within the burn at 13 temperature and 7 precipitation gauging stations, respectively, located along the altitudinal gradient (Fig. 1c) and (2) long-term monthly average precipitation (1931–2007) measured at two meteorological stations run by MeteoSwiss and located in the close vicinity of the burn, in Sierre (539 m a.s.l.) and Montana (1,508 m a.s.l.; Fig. 1b). Within the burn, temperature was measured with Thermochron iButtons (DS1922L with a resolution of 0.5°C; Maxim Integrated

Products, Sunnyvale, USA) fixed in pairs under a sunshade at 2 m above soil level. Precipitation was measured annually from June to September using Campbell rain gauges. Precipitation measurements were not possible during months with snowfall, i.e. October to May at the highest gauging station.

A monthly drought index (DRI) was calculated according to Thornthwaite (1948): $DRI = P - PE$, with P equal to the monthly precipitation sum, and PE equal to the estimated potential evapotranspiration in the same month, a function of monthly mean temperatures and geographical latitude. Values of DRI below zero indicate moisture deficits. Bigler et al. (2006) evaluated different drought indices for the Rhone valley and found no differences between the simple index of Thornthwaite and more mechanistic ones.

Data analyses

The distribution of seedling and sapling density as well as the distribution of herbaceous vegetation along the altitudinal gradient was modelled with generalized additive models (GAMs) using the ‘gam’ function of the R ‘mgcv’ library with Gaussian error distribution. Generalized linear models (GLMs) were then used to investigate the relationship between tree recruitment (number of seedlings and saplings 0–500 cm) in the first 4 years after the fire (2004–2007) and the factors altitude (m a.s.l.), availability of exposed mineral soil (%), moss cover (%), distance to the live forest edge (m) and thickness of the ash layer in 2004 (cm). Since the response variable was discrete (number of seedlings and saplings 0–500 cm), we fitted a GLM with Poisson distribution and log link. The predictors were standardised prior to the analysis. Stepwise model optimisation was used in order to select the most parsimonious model, i.e. variables were only added to the model if they were significant and the change in D^2 was $\geq 10\%$. Following the distribution of pre-fire forest communities along

the altitudinal gradient, seedling survival and mortality as well as the proportion of different tree species present in 2007 were calculated for each altitudinal zone (lower montane, upper montane and subalpine) separately. Linear regression was used to assess temperature and precipitation trends along the altitudinal gradient within the burn. The analysis focused on the spring months (April–June), the most important season for seedling establishment and tree growth in Scots pine and Norway spruce (e.g. Castro 2006; Pichler and Oberhuber 2007; Rigling et al. 2002). DRI's along the altitudinal gradient were calculated for the month of June only, because precipitation measurements were not possible in April and May. In contrast, long-term precipitation levels were analysed for the entire spring season as well as on an annual basis. Statistical analyses were done using the statistical computing system R Version 2.4.1 (R Development Core Team 2006).

Results

Tree recruitment along the altitudinal gradient

The density of tree seedlings and saplings (0–500 cm) per ha varied considerably along the altitudinal gradient with almost no seedlings below 1,100 m a.s.l. and a sharp increase above 1,600 m a.s.l. (Fig. 2a). In 2007, total numbers/ha (\pm SE) averaged 590 (\pm 148) in the lower montane zone (900–1,299 m a.s.l.) and 696 (\pm 139) in the upper montane zone (1,300–1,699 m a.s.l.), whereas an average of 2,821 (\pm 701) seedlings and saplings/ha were found in the subalpine zone (1,700–2,100 m a.s.l.). In all altitudinal zones, the majority of seedlings and saplings belonged to the deciduous pioneer species silver birch *Betula pendula* Roth., aspen *Populus tremula* L. and willow *Salix appendiculata* Vill. (900–1,299 m: 79.3%; 1,300–1,699 m: 97.4% and 1,700–2,100 m: 85.3%), while the PFSF species larch, downy oak, Scots pine and Norway spruce represented only a small portion (900–1,299 m: 12.4%; 1,300–1,699 m: 2.5% and 1,700–2,100 m: 14.4%). Resprouting was very sparse and was only observed in downy oak. In contrast to tree recruitment, revegetation of the understory occurred rapidly after the fire, and the average cover of herbaceous species exceeded 60% at all but the lowest altitudes in 2007 (Fig. 2b).

The number of tree seedlings and saplings (0–500 cm) was neither related to the thickness of the ash layer nor to the cover of mosses (Table 1). However, seedling and sapling densities of both PFSF and pioneer species increased with altitude. While the density of PFSF species was inversely proportional to the distance to the forest edge in the first 3 years after the fire, pioneer species showed a (positive) relationship with the distance to the forest edge

Fig. 2 **a** Number of seedlings and saplings (0–500 cm) of pre-fire stand forming and pioneer species, respectively, along the altitudinal gradient in 2007, 4 years after the stand replacing wildfire. Seedling and sapling densities along the gradient were modelled using generalized additive models (GAMs). **b** Revegetation at different altitudes in the first 4 years after the fire: curves represent mean cover of herbaceous species (black) \pm SE (light grey) modelled by GAMs. Vertical lines represent the distribution of the sampling plots along the altitudinal gradient

only in 2004. Seedling and sapling density was negatively related to the availability of exposed mineral soil in the first 3 years after the fire (PFSF: 2004–2005; pioneer species: 2005–2006).

The number of seedlings (0–10 cm) peaked in 2004 and then continuously decreased in the following years (Fig. 3). The abundance of tree seedlings was low in the lower and upper montane zones, but jumped in the subalpine zone. The mortality of PFSF seedlings was high in all altitudinal zones and in all years, mostly exceeding 60%. By contrast, annual seedling mortality in pioneer species was mostly lower than 25% in the first 2 years (it reached 39% in the lower montane zone in the second year) but increased in the third year and reached as much as 89% in the subalpine zone.

Table 1 Results of analysis of deviance on the effects of altitude (m a.s.l.), distance to forest edge (m), cover of exposed mineral soil (%), moss cover (%) and thickness of the ash layer in 2004 (cm) on the number of seedlings and saplings of pre-fire stand forming species

total number of seedlings present at the beginning of each period. **a** Pre-fire stand forming species (*Larix decidua*, *Picea abies*, *Pinus sylvestris* and *Quercus pubescens*); **b** pioneer species (*Betula pendula*, *Populus tremula* and *Salix appendiculata*)

Observations of cone production in Graechen and Gampel Steg near Leuk indicate that seeds of larch and Scots pine were available in all years, whereas Norway spruce failed to produce seeds in spring 2005 and 2006 (Table 2).

Climate along the altitudinal gradient

Air temperature and precipitation linearly changed along the altitudinal gradient within the burn (Fig. 4a and b; data shown for June only). The slopes of the regression lines were similar in all years, indicating that temperature and precipitation increments along the altitudinal gradient are reasonably constant. In June, differences in precipitation levels reached between 15 and 21 mm on a gradient of 1,000 m in the years 2005–2007, whereas temperatures

Table 2 Cone production of *Larix decidua*, *Picea abies* and *Pinus sylvestris* in two regions of the Rhone valley near Leuk, Switzerland, in spring 2004, 2005 and 2006 (data provided by A. Burkart)

<i>Picea abies</i>	Gampel Steg	2	0	0
	Graechen	1	0	0
<i>Pinus sylvestris</i>	Graechen	2	1	3

0, no cones observed; 1, <50% of trees produced cones; 2, 50% of trees produced cones; 3, >50% of trees produced cones (masting)

differed by 6.7–7.2°C. Similar differences along the altitudinal gradient can be found in the long-term precipitation measurements at the two meteorological stations in Sierre (539 m a.s.l.) and Montana (1,508 m a.s.l.). The difference

Fig. 4 Climatic differences along the altitudinal gradient in the burnt area in June 2005, 2006 and 2007. **a** Monthly precipitation sum; **b** Monthly mean temperature and **c** Drought index (precipitation–potential evapotranspiration): values below zero indicate moisture deficits

Fig. 5 Comparison of long-term precipitation levels (1931–2007) at two contrasting altitudes represented by the two meteorological stations Montana (1,508 m a.s.l.) and Sierre (539 m a.s.l.) in the vicinity of the burnt area (data from MeteoSwiss). **a** Spring precipitation (April–June); **b** annual precipitation. Vertical lines

in mean precipitation (1931–2007) between the two locations amounts to 70 mm in spring (April–June) and to 314 mm annually (Fig. 5). Even in the extremely dry year of 2003, precipitation at Montana exceeded the long-term average of Sierre (1931–2007) considerably. By contrast, the annual precipitation at Sierre did not reach the long-term average of Montana during the extraordinarily wet 2007.

The DRI showed marked differences in the amount of water available to plants along the altitudinal gradient at the end of spring (Fig. 4c). In June, water availability was 46–49 mm higher at 2,000 m than at 1,000 m a.s.l., depending on the year. In 2005 and 2006, years with moderately wet spring seasons (Fig. 5a), the potential evapotranspiration exceeded precipitation at 1,000 m a.s.l.

represent precipitation levels of individual years from 1931–2007, bold lines indicate the year of the burn (2003) and the first years after the fire (2004–2007). Grey curves represent a fitted normal distribution

by 48 and 62 mm, respectively, resulting in a clear water deficit. Even in the extraordinarily wet spring of 2007, precipitation exceeded the potential evapotranspiration only marginally at the lowest altitude. At higher altitudes, water was abundant in 2007, and the moisture deficit was small in 2005.

Discussion

During the last centuries, fire has played a minor role in shaping forest ecosystems in the Central Alpine valley of the Valais (Schumacher and Bugmann 2006), where 85% of the fires with known source of ignition are caused by humans (Zumbrunnen et al. 2009). Nevertheless, small

fires occur regularly in this region, and there is strong evidence that increasing temperatures and changes in forest use and management will lead to an increase in large fire events at low altitudes (Zumbrunnen et al. 2009). Modelling studies have already suggested that fire may become more important for forest dynamics in the Central Alps than changes in growth conditions due to global warming (Elkin et al. 2010; Schumacher and Bugmann 2006). Our study suggests that reforestation after large, stand replacing fires in the European Central Alps has to rely mainly on recruitment from seeds, both because high intensity fires destroy the seedling and sapling bank, and resprouting is not common in Scots pine and Norway spruce (Zasada et al. 1992). The fact that post-fire regeneration in Scots pine almost exclusively depends on seed rain from outside the burnt area is also known from Mediterranean areas (Habrouk et al. 1999). The sharp decline in the number of tree seedlings 2 and 3 years after the fire in Leuk indicates that the window of opportunity for tree recruitment is very short. This is consistent with studies in boreal forests (Charron and Greene 2002; Greene et al. 2004). The rapid spread of herbaceous species increased competition and reduced the availability of favourable seedbed (Wohlgemuth et al. 2002), which we consider to be the main reason limiting germination of tree seeds and early survival in our site 2 and 3 years after the fire. However, boreal studies suggest that the reduction in granivores by the fire may also be important (Charron and Greene 2002; Greene et al. 2004). Although short, the period of low competition after the fire was long enough for pioneer species such as aspen and willow. Their small, anemochorous seeds disperse over large distances (Braatne et al. 1996; Müller-Schneider 1986) and were thus able to reach the whole burnt area by the second year after the fire (Clark et al. 1998; McEuen and Curran 2004). By contrast, dispersal distances in the coniferous, PFSF species are smaller (Brown et al. 1988; Dovciak et al. 2008; Müller-Schneider 1986), and seed availability depends on the presence of live seed trees, as indicated by the negative correlation between the number of seedlings and saplings and the distance to the forest edge in our study (cf. Greene and Johnson 2000 and Keyser et al. 2008 for North American conifers). Moreover, seed availability in Scots pine and Norway spruce varies considerably between years (masting; Rohmeder 1972; Zackrisson et al. 1999). Since the window of opportunity for seedling establishment is short and seedling mortality was high in all years, abundant seed supply and favourable growth conditions in the first 2 years after a fire are crucial for successful tree recruitment.

Many studies in boreal forests of North America demonstrated a positive relationship between sapling density and fire intensity, which has been linked to the better performance of seedlings on soils with thin organic layers

as opposed to thick organic layers present after low severity fires (Greene et al. 2007; Jayen et al. 2006; Johnstone and Kasischke 2005; Turner et al. 1997; but see Keyser et al. 2008). Similarly, exposed mineral soil is considered as favourable seedbed after disturbance in European boreal forests (Brang 1998; Valkonen and Maguire 2005; Vanha-Majamaa et al. 1996), but it has been suggested that microclimatic conditions, especially water availability, are even more important for tree recruitment than seedbed type (Oleskog and Sahlen 2000; Vanha-Majamaa et al. 1996). In our study, tree recruitment was negatively related to the availability of exposed mineral soil in the first years after the fire. In contrast to windthrow disturbance in subalpine forests, where exposed mineral soil indicates low competition (Brang 1998; Wohlgemuth et al. 2002), this seedbed type seems to provide adverse growth conditions in the first years after a stand replacing fire. Recruitment success was independent of fire intensity in our study, which may be mainly due to the fact that the fire was severe in all parts of the Leuk burn. Consequently, the variation in fire intensity may have been too small to be relevant for seed germination and seedling establishment. Contrary to fire intensity and exposed mineral soil, post-fire seedling and sapling density increased with altitude in all years and both species groups. The sparse regeneration of Scots pine at lower altitudes in Leuk contrasts with several studies reporting fast and abundant post-fire recruitment of this species in European boreal forests (Hancock et al. 2009; Östlund et al. 1997; Zackrisson 1977), where water availability is rarely a limiting factor. Temperature and precipitation measurements in our site demonstrated that moisture deficits in the second and third years after the fire were considerable at lower and medium altitudes in June, even though precipitation levels in these years were above the long-term average. At higher altitudes, however, moisture deficits were small in the same years. Consequently, years with favourable moisture conditions for seedling establishment in spring are rare at low and medium altitudes, and successful seedling establishment requires precipitation levels far above the long-term average. Thus, we suggest that drought is the key limiting factor for tree recruitment after fire disturbance in the Central Alps. This is concordant with various studies showing that water availability in spring is one of the most important factors affecting germination, seedling establishment and tree growth in Scots pine and Norway spruce (Castro 2006; Castro et al. 2005; Pichler and Oberhuber 2007; Rigling et al. 2002), the main pre-fire species at low and medium altitudes in our site. Since the rise in temperature and the prolongation of drought periods are expected to continue during the coming decades (Beniston et al. 2007; IPCC 2007), windows of opportunity for tree regeneration after fire disturbance may become

increasingly rare at lower altitudes of the Central Alps. Scots pine forests in the lower montane zone of the Rhone valley have already been considered vulnerable to climate change because of their limited drought tolerance (Bigler et al. 2006; Rebetez and Dobbertin 2004; Weber et al. 2007). Based on observations in mature stands, Rigling and Cherubini (1999) suggested that dominant Scots pine will be replaced by the more drought-resistant downy oak with continued global change, whereas dynamic vegetation models go even further and predict the transition of these forests into steppe under climate change scenarios involving an increase in temperature of 4.7°C or more (Bugmann 1999). The failure of tree regeneration at lower altitudes in our study in years with precipitation levels above the long-term average indicates that such changes may be accelerated by disturbance events such as wildfires, which in turn supports the predictions by Schumacher and Bugmann (2006) and Elkin et al. (2010) that wildfires may become important for shaping forest ecosystems in the future even in areas where fire disturbance is currently low.

Acknowledgments We gratefully acknowledge field work by Sara Bangeter, Alexandra Bunge, Stefan Hadorn, Tabea Kipfer, Marlen Kube, Salome Leugger and Lukas Wohlgenuth and logistic support from Claudio Cattaneo, Dieter Trummer and Ulrich Wasem. We thank A. Burkart for providing the data on cone production, and Ilkka Vanha-Majamaa and Peter Brang for comments on the manuscript. The study was supported by the Dienststelle für Wald und Landschaft, Canton of Valais, Switzerland.
